

Attention

- By Polisetty Sai Teja

Recap

- **Embeddings first:** Transformers turn text into high-dimensional vectors called *embeddings*.
- **Lookup, not meaning (yet):** At this stage, an embedding is a learned lookup — the token “**mole**” maps to the same vector in every sentence.
- **What transformers add:** Through **attention**, the model reads surrounding words and **steers** each token’s vector toward the meaning required by its context.
- **Why it matters:** Context-aware vectors help the model both **understand neighbors** and **predict the next token** more accurately.

Same Token → Same Initial Embedding (Before Attention)

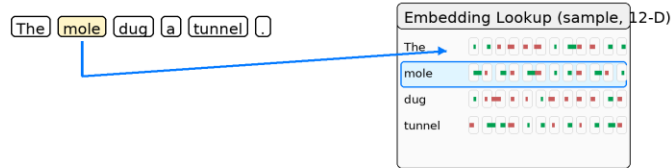

Before attention: every 'mole' maps to the same embedding row (lookup).

Core Idea of Attention

Context-free Embeddings (Before Attention)

Text → tokens → ID → lookup vector (no context yet)

All 'mole' tokens map to the same initial embedding row.

Start point: Tokens begin as context-free embeddings (look up vectors).

What Attention Does: Weighted Information Pull

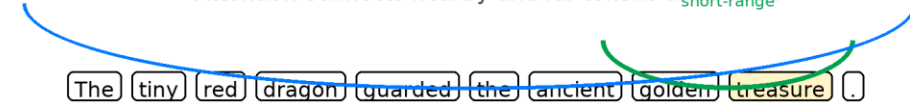

Each token gathers from others with learned weights → ΔE → new embedding

What attention does:
Each token computes how much to pay attention to every other token and pulls in their information as a weighted sum—producing a context-specific update (ΔE) to its embedding.

Short- and Long-Range Information Flow

Attention connects nearby and far tokens as needed

Short & long range: These weights connect both nearby words and far-apart words, so information can jump across the sequence (short- and long-distance dependencies).

Core Idea of Attention

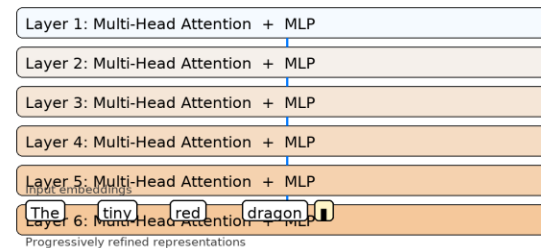

Meaning Emerges from Context (Same Token, Different Meanings)

Meaning via context: The same token (e.g., *mole*) is steered to different regions of the space depending on its neighbours—animal vs chemistry unit vs skin lesion.

Deep Refinement: [Attention + MLP] × L Layers

Representations grow more abstract with depth

Deep refinement: Repeat in attention (plus MLPs) over many layers progressively sharpens meaning.

Next-Token Prediction Uses the Last Position

Final hidden state at last position → Linear → Logits → Softmax → Next token

$$y = \text{softmax}(W_{out} \cdot h + b)$$

- Prediction:** For next-token prediction, the model uses the **final, last-position representation** produced after all layers.

Single-Head Attention - What & Why

Goal: Let a token "borrow" the right info from other tokens.

Projections: $Q_i = E_i W_Q$, $K_i = E_i W_K$, $V_i = E_i W_V$

Scores: $s_{ij} = \frac{Q_i \cdot K_j}{\sqrt{d_k}}$ (apply causal mask if predicting left→right)

Weights: $a_{ij} = \text{softmax}_j(s_{ij})$

Update: $\Delta E_i = \sum_j a_{ij} V_j$; output = $E_i + \Delta E_i$

Intuition: Q = what I'm looking for, K = what I offer, V = what to send.

Values: $V = E \cdot W_V$

v_1	1.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00

Context contributions (ΔE_i) at each position

ΔE_1 ΔE_2 ΔE_3 ΔE_4 ΔE_5 ΔE_6 ΔE_7 ΔE_8 ΔE_9 ΔE_{10}

Add updates to embeddings

$E_1 + \Delta E_1 = E_1'$

$E_2 + \Delta E_2 = E_2'$

$E_3 + \Delta E_3 = E_3'$

$E_4 + \Delta E_4 = E_4'$

$E_5 + \Delta E_5 = E_5'$

$E_6 + \Delta E_6 = E_6'$

$E_7 + \Delta E_7 = E_7'$

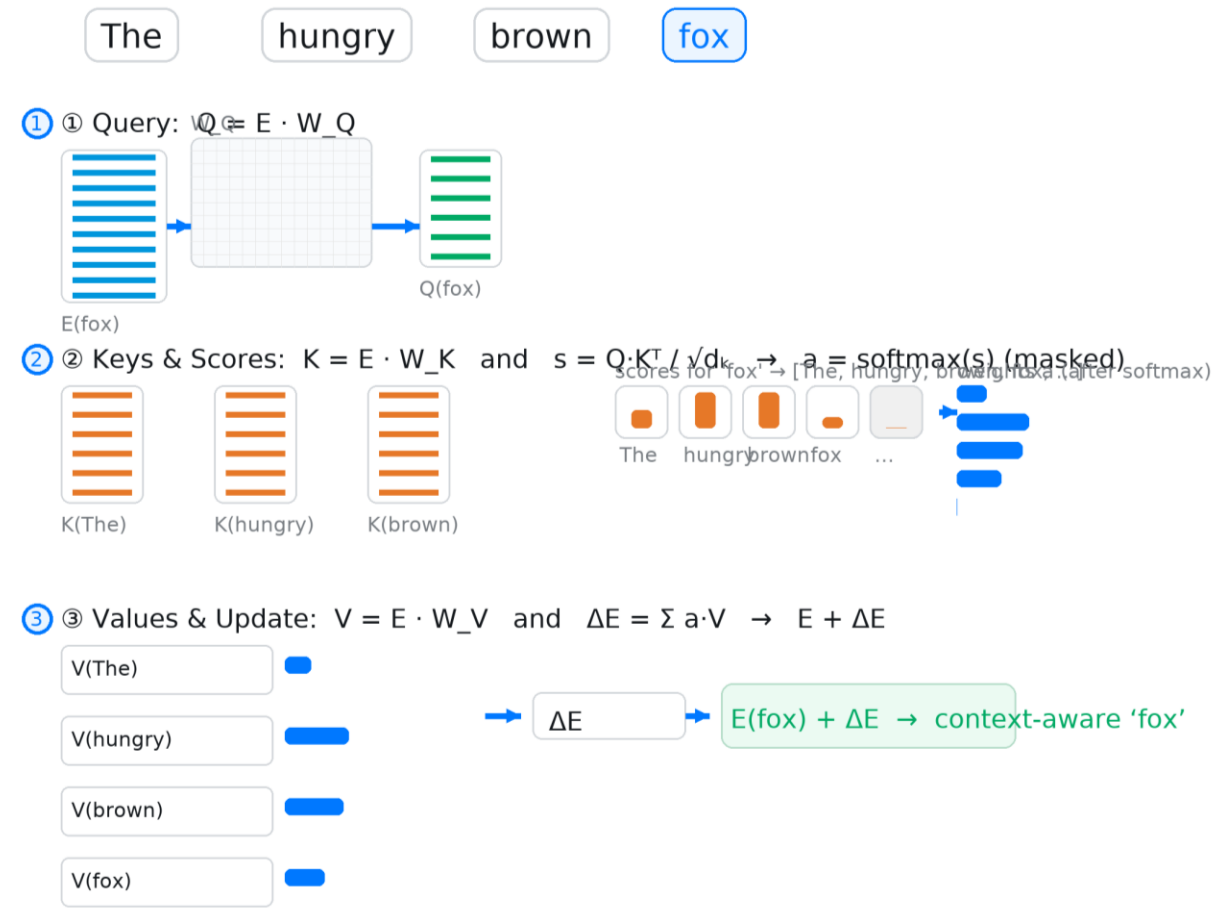

$E_8 + \Delta E_8 = E_8'$

$E_9 + \Delta E_9 = E_9'$

$E_{10} + \Delta E_{10} = E_{10}'$

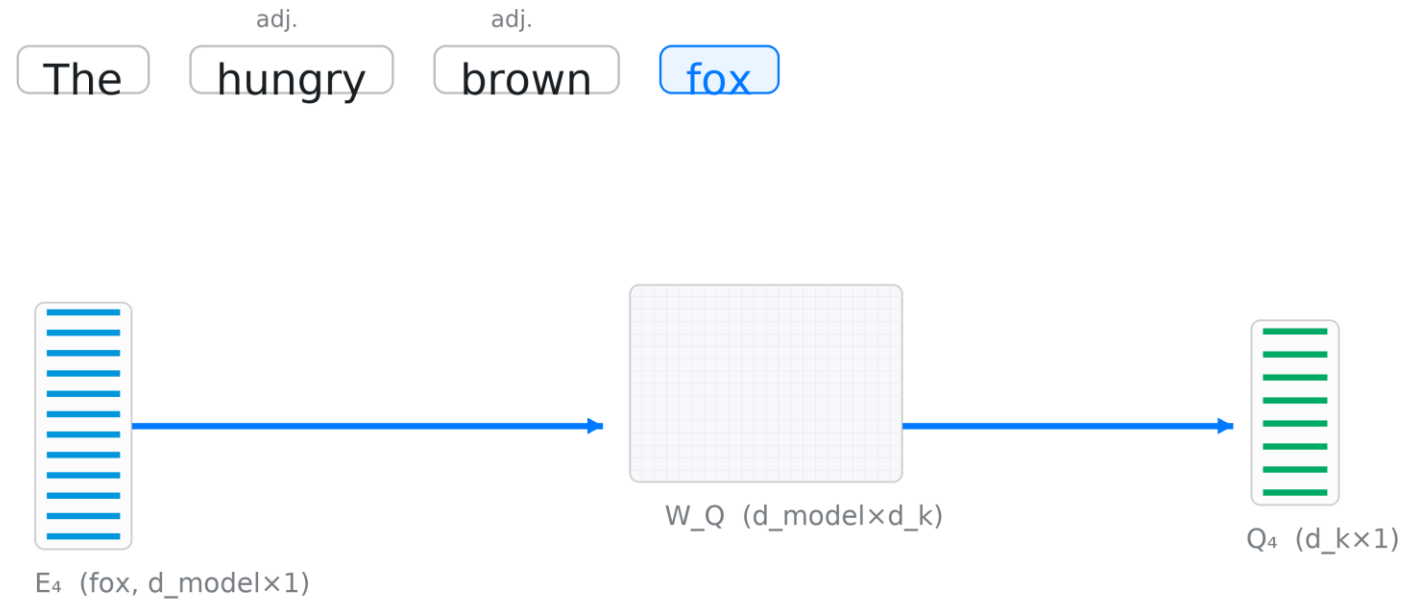

Single-Head Attention - Cont...

- **Step 1** — Build the Query (Q)
 - Target token: “fox” in “The hungry brown fox jumped over the sleepy dog.”
- **Step 2:** Keys (K_i) + “I’m an adjective” tagging
- **Step 3:** Scores(Dot product $Q \cdot K \rightarrow$ relevance score) + scaling (attention weights - probability distribution) + causal mask(prevents future words from leaking information) \rightarrow weights
- **Step 4:** Weighted sum of Values $\rightarrow \Delta E \rightarrow$ updated ‘fox’ - **attention pattern grid**
- **Step 5:** Update the embedding.

S1: Query Vector

- Idea: At “fox”, the model forms a question: “Are there adjectives before me?”
- **Operation:** $Q_4 = E_4 \cdot W_Q$ projects the “fox” embedding into a **query space** (d_k e.g., 128)
- **Why:** Q_4 encodes what “fox” should look for (modifiers like **hungry**, **brown**).
- **Scope:** We compute a **query Q_i** for **every** token; we’re highlighting Q_4 only for clarity.

Build the query for the focus token: $Q_4 = E_4 \cdot W_Q$

Query vector - cont....

The hungry brown fox jumped over the sleepy dog .

Embeddings E_i (one per token)

apply to every E_i

W_Q (shared)

$$Q_i = E_i \cdot W_Q \text{ for } i = 1 \dots n$$

example focus

Key vector

Idea: Each token advertises what it is. For our head, adjectives like hungry, brown, sleepy emit a “I’m an adjective” signal so nouns (e.g., fox, dog) can find them.

Operation: $K_i = E_i \cdot W_k$

- E_i : embedding of token i (size d_{model})
- W_k : learned, shared projection matrix ($d_{\text{model}} \times d_k$)
- K_i : key in the same d_k space as queries, so dot products $Q \cdot K$ are comparable

Why: Queries need something to match against. Keys are the comparators—learned directions that make the “**right**” **tokens align with the current token’s intent** (e.g., a noun’s query aligns with adjective keys). Without keys, the model couldn’t score who to attend to.

Scope

- We compute a key K_i for every token using the same W_k
- Different heads learn different “advertisements” (adjective-ness, subject-verb links, coreference, etc.). This step is independent of masking; masking affects scoring later, not key creation.

Compute keys for every token: $K_i = E_i \cdot W_K$ — keys advertise what each token offers to others.

S2: Key vector

Conceptually, Key vector is **answer** of query vector when both are in the same direction.

S3: Scores -> Mask -> Weights (queries vs keys)

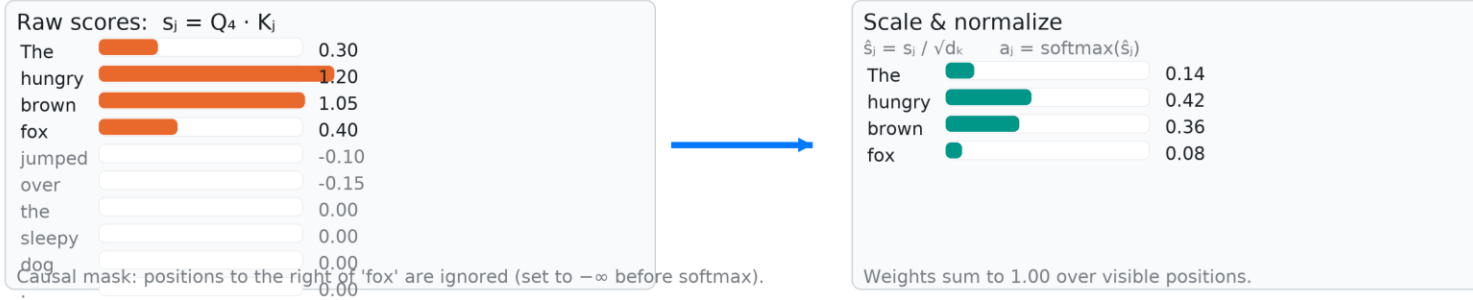

- **Idea:** Turn “what I’m looking for” (Q) and “what I offer” (K) into match scores, then mask future positions, and finally apply softmax to get attention weights.
- **Operation:**
 - i is the current position (here we illustrate $i=4$ the word “fox”).
 - Mask all positions $j>i$ (future tokens) before softmax in a decoder block.

$$s_j = \frac{Q_i \cdot K_j}{\sqrt{d_k}}$$
$$a_j = \text{softmax}(s)_j$$

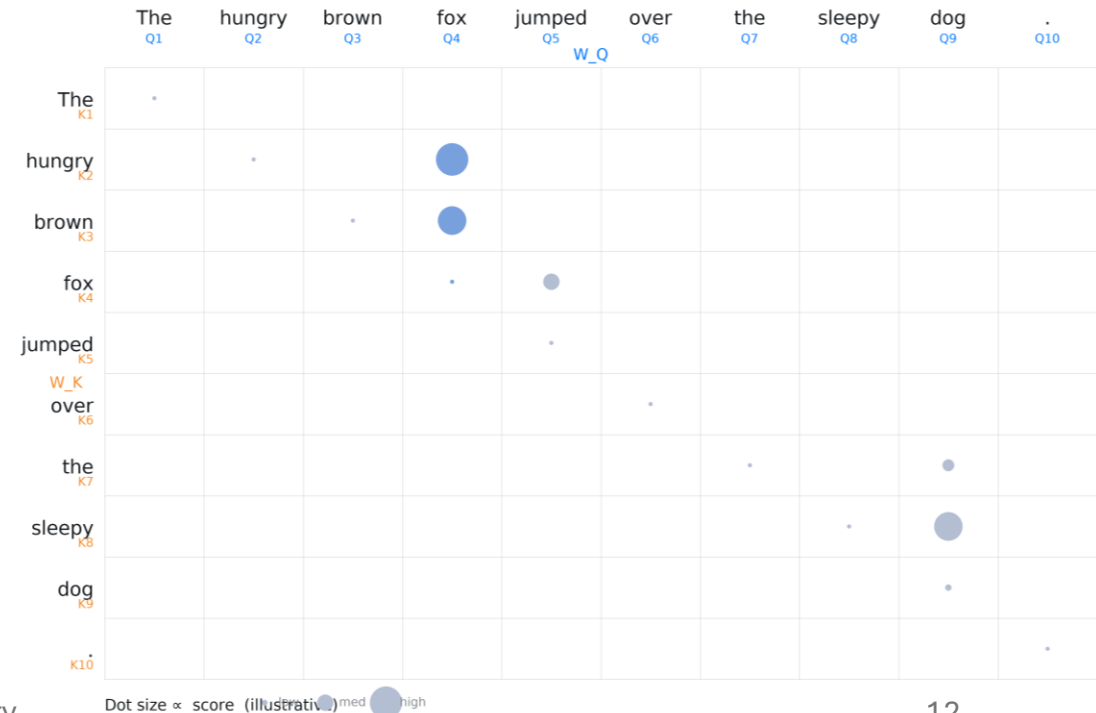

The ^{adj.} hungry ^{adj.} brown **fox** jumped over the ^{adj.} sleepy dog .

Target query: Q₄ (fox)

Step 3: scores \rightarrow mask \rightarrow softmax. Example for Q₄ ('fox'): focus lands on adjectives 'hungry' and 'brown'.

ATTENTION PATTERN

Why

- The dot product measures **alignment** between the current token's intent and other tokens' signals.
- Scaling by $\sqrt{d_k}$ stabilizes training.
- Softmax produces a **probability distribution** (weights) over allowed positions that sum to 1.

Scope

- Do this for **every position** i.
- Masking policy depends on architecture: **causal** (decoder-only) vs **bidirectional** (encoders don't mask).

** Context Size

- size of attention pattern is same as that of context size.
- Hence context is not scalable, but to work on it different mechanics came into picture like
 - Sparse attention mechanism
 - Blockwise attention
 - Linformer
 - Reformer
 - Ring attention
 - Long former
 - Adaptive attention span

S4 : Values $\rightarrow \Delta E \rightarrow$ Updated Embedding

- Idea: Use the attention **weights** to mix **value vectors** V_j . The result is a **context vector** C_i that captures what the current token needs from others. Project it (optional W_O) and **add** to the original embedding.

- Operation:

$$V_j = E_j W_V$$

$$C_i = \sum_j a_{ij} V_j$$

$$\Delta E_i = C_i W_O \quad (\text{optional head output proj})$$

$$E'_i = E_i + \Delta E_i \quad (\text{then LayerNorm in the block})$$

Why

Values carry the information to transfer (e.g., the adjectives' descriptors). The weights decide how much of each value flows to the current position. Adding ΔE_i steers the embedding in a context-aware direction.

Scope

This happens for every token and for every head in the layer. Multi-head outputs are concatenated and projected before the residual add & LayerNorm.

	The	adj. hungry	adj. brown	fox	jumped	over	the	adj. sleepy	dog	.
	E1 ↓ Q1	E2 ↓ Q2	E3 ↓ Q3	E4 ↓ Q4	E5 ↓ Q5	E6 ↓ Q6	E7 ↓ Q7	E8 ↓ Q8	E9 ↓ Q9	E10 ↓ Q10
E1 The				0.14 v1						
E2 hungry				0.42 v2						
E3 brown				0.36 v3						
E4 fox				0.08 v4						
E5 jumped				0.00 v5						
E6 over				0.00 v6						
E7 the				0.00 v7						
E8 sleepy				0.00 v8						
E9 dog				0.00 v9						
E10 .				0.00 v10						

Value matrix (white): each row forms $v_i = E_i \cdot W_V$ (left). The highlighted 'fox' column shows its attention weights \times value labels.

When we multiply **VALUE MATRIX** with the embedding, we can think of it as saying, if this word is relevant to adjusting the meaning of something else, what exactly should be added to embedding of something else.

****Keys and queries are not needed once u get the attention pattern.**

$$E_4 = E_4 + \Delta E_4$$

Attention adds ΔE_4 (from hungry/brown), giving E_4' — a co

Multi-Head Attention - Big Idea

- Idea
 - Single head attention * 10,000 = parallel ops
 - Each head with its own key/query/value matrices, so it can learn a **different relation** (e.g., adjectives → nouns, subject → verb, long-range links).
 - GPT-3 has 96 attention heads inside each block = 96 attention patterns

Operation:

For each head h :

$$Q^{(h)} = E W_Q^{(h)}, \quad K^{(h)} = E W_K^{(h)}, \quad V^{(h)} = E W_V^{(h)}$$

$$A^{(h)} = \text{softmax}\left(\frac{Q^{(h)} K^{(h)\top}}{\sqrt{d_k}}\right), \quad C^{(h)} = A^{(h)} V^{(h)}$$

Concat all head outputs and project:

$$\text{MHA}(E) = [C^{(1)} \parallel \dots \parallel C^{(H)}] W_O$$

Residual add & LayerNorm finish the block:

$$E' = \text{LayerNorm}(E + \text{MHA}(E))$$

Combine heads: per-head updates add into ΔE_i , then $E_i \leftarrow E_i + \Delta E_i$

Original embedding $E_i + \Delta E_i^{\{1\}} + \Delta E_i^{\{2\}} + \Delta E_i^{\{3\}} + \Delta E_i^{\{4\}} + \dots$

$\rightarrow E_i'$ (concat heads $\rightarrow W_O$, then residual add & LayerNorm)

Multi-Head Attention – cont...

Why this works

- Different heads specialize (syntax, agreement, long-distance references, etc.).
- Parallel heads = richer, disentangled signals per token.
- Scales well: GPT-3 uses **96 heads per block** (we illustrate with 4 for clarity).

Scope

- Heads run **for every token** and **at every layer**.
- The mechanism is identical to single-head; only the number of projections changes.

Connect to the "big model" numbers cont

- Total weights = 175,181,291,520
- Organized into 27,938 matrices

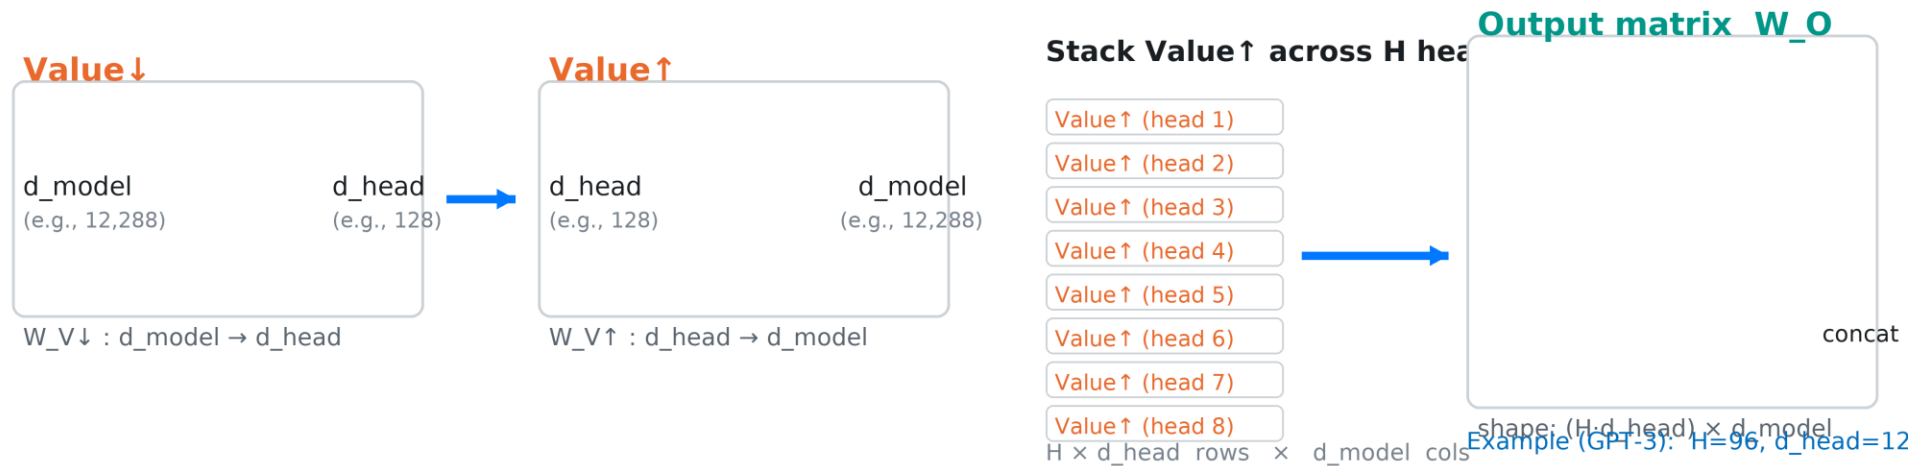

Matrix name	Matrix dimension
Embedding	$D_embed * n_vocab$ $12,288 * 50,257 = 617558016$
Key	$12,288 * 128 = 1,572,864 * \mathbf{96}$
Query	$12,288 * 128 = 1,572,864 * \mathbf{96}$
Value	$12,288 * 12,288$ (wrong) $128 * 12,288 = 1,572,864 * \mathbf{96}$ And $12,288 * 128 = 1,572,864 * \mathbf{96}$
Output	
Up-projection	
Down-projection	
UnEmbedding	$n_vocab * D_embed$ $50,257 * 12288 = 617558016$

Output Matrix

- Inside attention, each head uses two “value” projections:
 - **Value↓ ($W_{V\downarrow}$)**: projects the model width to the head width
 $W_{V\downarrow} \in \mathbb{R}$ (e.g., $12,288 \rightarrow 128$)
 - After attention mixes values, each head must return to model width via **Value↑**.
Collecting **all heads’ Value↑** blocks into one big projection is the **output matrix**
 $W_O \in \mathbb{R}^{(H \cdot d_{\text{head}}) \times d_{\text{model}}}$.

Output matrix (W_O): the ‘Value↑’ from ALL heads assembled into one projection

Docs usually say “value matrix” to mean Value↓ ($d_{\text{model}} \rightarrow d_{\text{head}}$). W_O is the big map back to d_{model} .

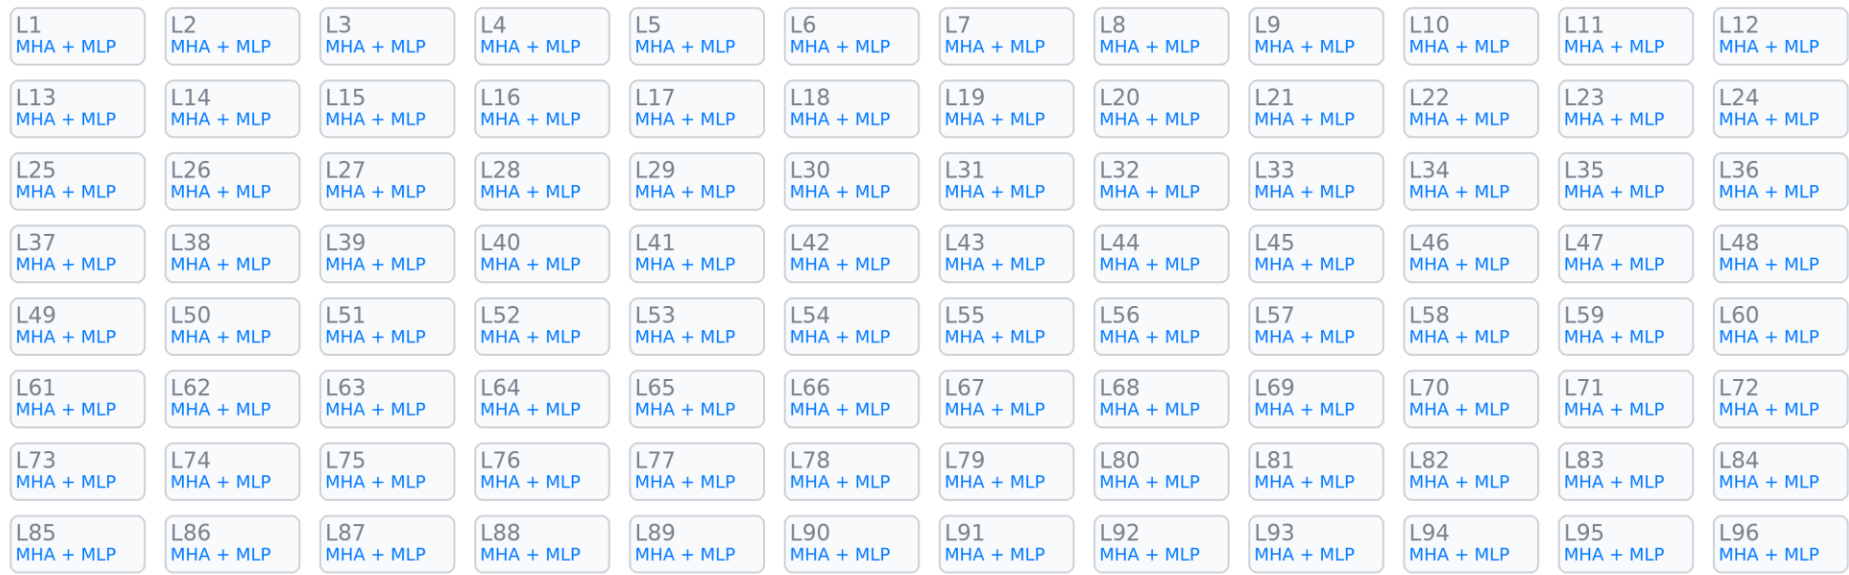

Takeaway: when someone says “the value matrix,” they usually mean Value↓. The ‘value up’ pieces across heads are assembled into a single Output matrix W_O that maps the concatenated head output

Beyond attention: the full Transformer block

- Data doesn't stop at attention; each block has Multi-Head Attention → residual+LayerNorm → MLP → residual+LayerNorm.
- The MLP is position-wise (same weights at every token), typically widening by 2–4× then projecting back down.
- Depth builds meaning
 - Blocks are repeated many times (e.g., GPT-3 uses 96 layers).
 - As we go deeper, embeddings absorb richer context from other embeddings that are themselves improving—enabling higher-level abstractions (sentiment, tone, genre), not just grammar.

Deep Stack: repeated blocks (e.g., 96 layers in GPT-3)

As depth increases:

- lower: local grammar / short-range links
- middle: long-range dependencies, entities
- higher: topic, sentiment, tone, genre (poem vs. research)

Transformer Block: Multi-Head Attention + MLP (with residuals & LayerNorm)

E (token embeddings, all positions in parallel)

Multi-Head Attention

Q,K,V per head → attention → concat → W_O

Residual Add + LayerNorm

Position-wise MLP

2-4 × width up-proj → nonlinearity → down-proj

Residual Add + LayerNorm

Output of block → feeds next block (same for every token).

Parallelism:

- Across tokens (matrix multiplies over the whole sequence)
- Across heads (dozens of heads per block)

→ GPUs exploit this for scale and throughput

Connect to the "big model" numbers cont

Total studied params so far: ~58B parameters

Yet to study params: ~ 117B parameters

What's next? - MLP layers ...

Where the parameters live (attention vs other)

Attention params (K/Q/V + Output)
≈ 57,982,058,496 (≈58B) ≈ one-third

Other params (MLPs, embeddings, layer norms, etc.)
≈ two-thirds of total

Takeaways

- Attention is powerful for routing information, and it parallelizes well across tokens & heads.
- Most parameters come from the MLPs (big up/down projections at each layer).
- Scaling works because GPUs handle the large matrix multiplies in parallel.
